Coloring Graphs With a General Heuristic Search Engine

1 Introduction

When faced with a combinatorial optimization problem, practitioners often turn to black-box search heuristics such as simulated annealing and genetic algorithms. In *black-box optimization*, the problem-specific components are limited to functions that (1) generate candidate solutions, and (2) evaluate the quality of a given solution. We have been investigating whether it pays to develop a more sophisticated, general-purpose heuristic optimization engine. The issue is whether a substantial performance improvement or ease-of-use gain results from using such an engine over the näive implementation of search heuristics.

The case for well-engineered optimization engines has clearly been made for linear programming, where commercial LP packages (such as CPLEX) significantly outperform homegrown implementations of the simplex algorithm. The answer is not so clear for local search heuristics. A review [2] of six existing black-box optimization packages describes generally disappointing results.

Our system, *Discropt* [4], is intended as a general-purpose platform to experiment with heuristic optimization. Characteristics of *Discropt* include:

- *Ease of Use* – The system is designed to provide general data structures, search heuristics, and visualization tools to speed the development of algorithm implementation and minimize the need for performance tuning.
- *Flexibility* – The system is designed to be applicable to a wide range of optimization problems. In [4], we apply our system to six significantly different optimization problems: traveling saleperson, shortest common superstring, graph bandwidth, maxcut, maximum satisfiability, and vertex cover.
- *Awareness of Time* – The most effective heuristic to use for a particular problem is clearly is a function of the size of the instance, the power of the computer, and the time alloted for computation. Our system actively manages the alloted time to return the best answer possible in the given window.

In this paper, we report on our experiences building implementations of vertex coloring and graph bandwidth coloring with *Discropt*. We use the same problem-independent heuristic implementations reported in [4] without fundamental changes or problem-specific tuning. Adapting our heuristics to graph coloring problems provides a good test of the flexibility of our system for two reasons. First, graph coloring is well known as a very challenging problem for local search heuristics such as employed within our system. Second, the fundamental solution representation for graph colorings (set partitions) had not been implemented in our system as of [4]. In this paper, we

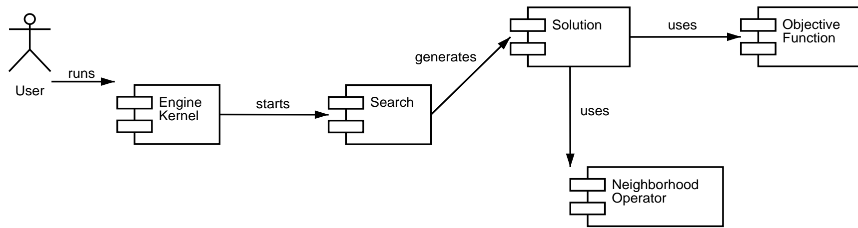

Figure 1: Basic system flow

test the performance of optimization routines developed for permutation and subset problems on a completely different class of object.

Our organization is as follows. In Section 2, we briefly report on the architecture of our system. In Section 3, we discuss an important issue in heuristics for graph coloring, namely the trade-off between quality (number of colors) and validity (number of edge-violations) in partial solutions. We present an general method for combining the two objective functions such that (1) requires no problem-specific information from the programmer, (2) enables us to optimize over the full solution space instead of restricting movement to correct examples, and (3) guarantees termination with valid solutions for all problems in a large and well-defined class. In Sections 4 and 5 we report on our experimental results for vertex and bandwidth coloring, respectively.

We emphasize that the goal of *Discropt* is significantly reducing the development time to build *reasonable* optimization routines for a widely varying problems. Our generality naturally exacts a tax on performance – we cannot expect our general optimization routines to compete with carefully crafted, problem-specific algorithms. One of the goals of our participating in this workshop is to assess our results against the highly-engineered problem-specific programs that we anticipate will represent most of the other submissions.

2 System Architecture

The architecture of *Discropt* has evolved somewhat since the reported in [4]. We outline the four central components of the system, a more complete system description is available online at [3].

- *Solution objects* are defined by (1) a combinatorial structure such as a permutation, subset, or set partition; (2) an objective cost over this structure; (3) a mechanism to disallow further generation of solutions when time is up. The combinatorial structure is separated from the solution implementation so that new types can be easily added. Incrementally constructive heuristics are supported through *partial solutions*, which can be *extended* by inserting an element into any position of the combinatorial structure.

- *Neighborhood objects* implement the function of a neighborhood operator. Its separation from the other components make it easy to experiment with different types of neighborhood operators. Currently, we use a *swap* operation that exchanges two random elements of a combinatorial structure. The specifics vary from one structure to another. Together, *solution* and *neighborhood* capture the notion of a search space.

- *Search objects* define an exploration through the search space. The system currently includes a few basic heuristics, namely *hill climbing*, *simulated annealing*, and *incremental greedy*. In this paper, we will consider two different flavors of simulated annealing: (1) the basic

annealing algorithm with a time-sensitive exponentially cooled temperature schedule, and (2) simulated annealing with a restart mechanism that resets the temperature after the search reaches a local optimum. The incremental greedy heuristic extends a solution by picking the best partial solution from a pool of candidates. It is made time-sensitive by controlling the number of candidate partial solutions at each incremental step.

- *Objective function objects* are defined by users to compute the objective value of a solution in the search space. Optionally, a faster *delta* function can be defined to speed up local search.

  Although certain problems such as traveling salesman on complete graphs only have valid solutions, problems such as graph coloring have two dimensions: validity and cost. The user has the option of defining *validity* and *delta-validity* functions that measure the relative validity of a given solution.

These components together define the performance of a search. In [4], we demonstrated that simple combinations of the heuristics themselves can outperform each individual one.

3 Combining Cost and Validity Objective Functions

Problems whose search space contains invalid solutions (including both vertex coloring and bandwidth coloring) pose a special challenge for heuristic optimization. Considering invalid solutions seems essential to avoid getting trapped in local minima, and yet we need to ensure that the final solution is valid.

One approach is to define an ad-hoc objective function that *internally* combines the cost and validity. To ensure that the search terminate on a valid solution, the combined function must have the property specified by Johnson et. al., [1], that a locally optimal solution with respect to the objective function must always be valid.

The design of a correct combined function requires deeper understanding of the specific problem than we assume users of *Discropt* necessarily possess. Separate definitions of cost and validity are inherently more intuitive and natural than any combination of them. For example, the validity of a coloring can be measured by counting the number of edges whose vertices have the same color. We believe that maintaining this separation allows the user refine his understanding of the problem and develop with better definitions of validity as the project progresses. Instead, we propose a general approach to combining cost and validity functions which guarantees ultimate solution validity for a large class of problems while requiring no specific action on the part of the user.

We say that a problem P is *validity-monotonic* under a given neighborhood operator and validity function v if every solution that is not optimally valid with respect v has a more valid neighboring solution. Graph coloring under the swap neighborhood clearly has this property, since we can always swap any offending vertex to a new part of the partition. This increases the number of colors by one, but improves validity. There is always a path from any set partition to a valid solution. Validity-monotonic problems include vertex/set cover, independent set, and maximum clique under the swap neighborhood with natural validity functions.

Proposition 1 *Let P be a* validity-monotonic *under a given neighborhood operator with validity function v. Consider the linear objective function f, where*

$$f(s, c, v) = c(s) + k \cdot v(s)$$

and c and v are cost and validity functions respectively evaluated on candidate solution s, and k is a dynamically updated variable

$$k > \max \frac{|c(s_i) - c(t_i)|}{|v(s_i) - v(t_i)|} \quad (1)$$

for all s_i and t_i which are neighbors and are visited in the ith step by the search process in its exploration of the search space. Then, any solution s that is locally optimal with respect to f is globally optimal with respect to validity.

Proof: Suppose s is locally optimal with respect to f, and that its validity is not globally optimal. Then there is a neighboring solution t such that $f(s) = c(s) + k \cdot v(s) \leq c(t) + k \cdot v(t) = f(t)$ and $v(s) > v(t)$. This implies that $0 < k \cdot (v(s) - v(t)) \leq (c(t) - c(s))$ or $0 < k \leq \frac{c(t)-c(s)}{v(s)-v(t)}$, which is a contradiction to the definition of k. ∎

Such a combined function f allows the search to proceed through the search space improving cost, while always preferring valid solutions to invalid ones. In a more sophisticated setting, k may be set to converge to an upper bound of the dynamic maximum so that $k \to \epsilon + \max \frac{|c(s)-c(t)|}{|v(s)-v(t)|}$, after a certain number of steps. In other words, k can be made sensitive to search time so as validity is less emphasized at the beginning, more at later stages, and is optimally achieved at the end.

In our experiments where instances are run in 2, 20, and 100 seconds, validity is achieved in most cases except in a few instances of 2-second running times when the heuristics do not have sufficient time to explore the whole neighborhood of their local optima.

4 Experimental Results: Graph Coloring

The experiments are run on a low-end PC of 1Ghz Athlon K7 AMD processor, 768MB of RAM, and under the RedHat 7.2 operating system. Data are obtained from mat.gsia.cmu.edu/COLORING02/. We do not run 5 of them as the results are not meaningful for 100 second running times. In the interest of space, we do not show instances for which performance does not improve much between 2 and 100 seconds. The rest of the data are shown in table 1 and 2.

The combinatorial structure of a graph coloring is a set partition on the set of vertices, with each part representing a distinct color. A neighbor of a given coloring contains exactly one vertex with a different color. Our neighborhood operator selects a random vertex and assigns to it a random color $r, 1 \leq r \leq p+1$, where p is the number of existing colors. If a vertex with color of cardinality 1 is assigned a new color, the number of colors get reduced by 1. If $r = p + 1$ the number of colors gets increased by 1. We consider graph coloring under three different objective functions:

1. An external combination (described in Proposition 1) of simpler cost and validity functions, where the cost is the number of colors, and validity is the number of edges whose vertices have the same colors.
2. An external combination of the cost and validity components of [1] and equation 2 below, automatically combined using Proposition 1. Cost is $-\sum c_i^2$ and validity is $\sum 2 \cdot c_i \cdot e_i$.
3. An internally combined cost function, studied by Johnson et. al. [1]:

$$-\sum c_i^2 + \sum 2 \cdot c_i \cdot e_i \quad (2)$$

   where c_i denotes the number of vertices of color i, and e_i is the number of edges whose vertices have color i. As proven in [1], any locally optimal solution with respect to this function must be a valid solution.

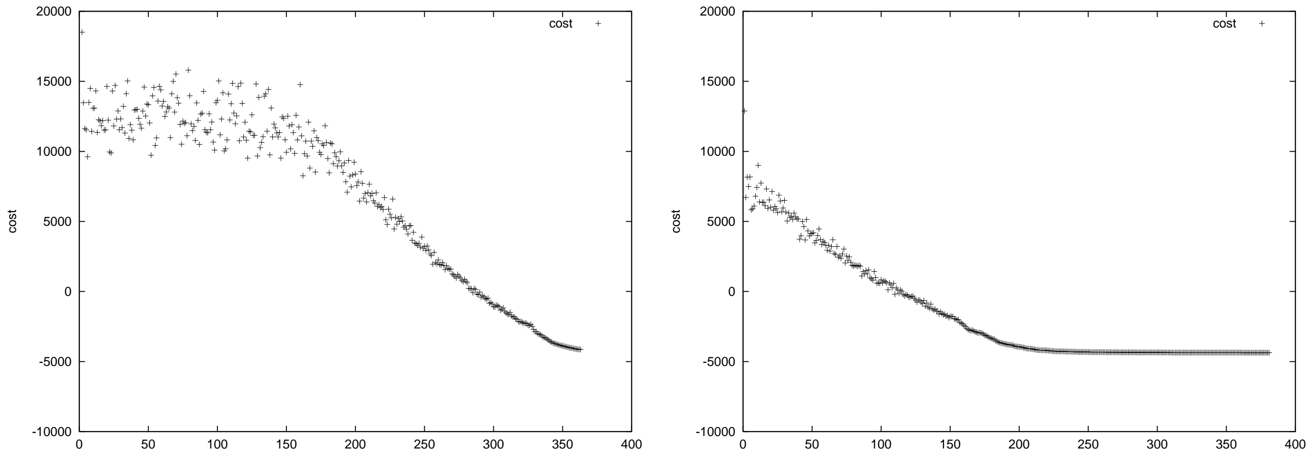

Figure 2: Cost (see equation 2) vs. running time (in seconds): simulated annealing on r500.5 before (left) and after (right) readjustment of temperature schedule.

The results in table 1 show the number of colors used for each of the three versions at 3 different running times. The performance gets expectedly better at longer running times. Secondly, the third version of objective function, equation 2, performs better than the simple objective function (first version) despite the first being much simpler to implement. The second version performs slightly worse than the third.

Table 2 compares four heuristics at 100-second running time. The results here are quite different from those reported in [4] for six other optimization problems. Greedy heuristic does not do as well as the others. Hill-climb performs surprisingly well at 100-second running time.

Running times:	120	240	480	960
hill climb	69	67	69	66
simulated annealing	146	66	66	72
simulated annealing with restart	149	141	102	64
incremental greedy	217	205	141	99
simulated annealing w. readjusted schedule	65	63	63	61
simulated annealing w. restart, readjusted schedule	69	65	63	62

The above table shows comparative performance of heuristics for the benchmarking instance r500.5. The results are medians of 5 different runs. Hill climbing does not perform appreciably better with longer running times, which means it has reached its potential at 120 seconds. The next three heuristics do rather badly by comparison, but do improve with longer times. We suspect this is due to a more difficult landscape of this instance. Shown in figure 2, simulated annealing takes much time to explore the landscape before converging. It seems the landscape requires very precise automatic time-sensitive adjustments. Adjusting the annealing schedule to be more aggressive results in better performance. This is the cost of automating a time-sensitive schedule.

5 Experimental Results: Bandwidth Coloring

The combinatorial structure of bandwidth coloring is a different from classical unordered set partitions, since it is possible to have colors i and j with $i < j$ and no color in between. Our neighborhood

Table 2: Comparison of four heuristics at 100-second running time. The * symbol means the time-sensitive component of the heuristic finds that it does not have enough time to run meaningfully.

operator is defined similarly to that of vertex coloring.

We use the following definitions of cost and validity. Cost is defined as the number of colors used, while the validity $v(G)$ is defined as $v(G) = \sum_{(u,v)\in E} \max\{0, d_{uv} - |c(u) - c(v)|\}$, where d_{uv} is the bandwidth limit of each edge (u, v) and $c(u)$ is the color at vertex u.

This definition together with the neighborhood operator favor local search heuristics that defines a smooth transition of validity over incremental greedy heuristic that requires validity for each partial solution at each incremental step. The results show the performance of the three heuristics. Simulated annealing with restarts and hill-climb are slightly ahead of of simulated annealing.
